ABSTRACT

Aircraft often include a central memory which distributes data to a number of communication, navigational and other utilization devices. In order to achieve a high degree of security for data transmission from the memory to the utilization devices, data subsets are distributed to the utilization devices in parallel so that any radiation generated from the parallel branches results in superposition of individual data signals. In effect, a jumbled resultant signal is produced which is difficult or near impossible for unfriendly surveillance equipment to decipher.

4 Claims, 4 Drawing Sheets
FIG. 1
PARALLEL TRANSMISSION TO MASK DATA RADIATION

FIELD OF THE INVENTION

The present invention relates to data distribution, and more particularly to a distribution system for securely distributing data within an aircraft between an external source and an aircraft data system.

BACKGROUND OF THE INVENTION

In the daily preparation of military aircraft, it is often necessary to store regularly updated security codes, known as crypto-variables or keys into weapon control and other communication systems such as friend or foe identification systems (IFF). This task is currently performed by a portable code storage box which is connected to an aircraft code memory device by means of conventional pin connectors. In the naval fleet this transfer of security codes to an aircraft is done during pre-dawn hours in all types of weather and sea conditions. On an aircraft carrier, this is manually performed by a cryptocustodian to aircraft that rests on the flight and hangar decks.

Although the procedure is generally satisfactory, it is a time-consuming one requiring proper connector hook-up between aircraft and the custodian's portable security code box. Due to the harsh environment, connectors often deteriorate and the reliability of the connectors is limited. Typically, such connectors are called upon to transfer digital security codes to an internal code memory of the aircraft. When the connectors between the portable code box and the aircraft evidence physical or electrical deterioration, errors in code transfer are possible.

In my co-pending patent application Ser. No. 224,605, a coupling device was disclosed which preferably magnetically transfers data and circuit power to an aircraft security code storage circuit without the inclusion of mechanical pin connectors. In the environment of an aircraft, the conventional custodian's security code portable transfer box is equipped with a sending unit which is magnetically attached to the exterior of an aircraft skin. At an aligned position along the interior surface of the skin is a receiving pick-up unit which magnetically picks up the digital code and low voltage power being transferred by the sending unit. The sending unit is easily removed after signal and power transfer have taken place by simply detaching it from the aircraft. As will be appreciated, such a simple and elegant technique avoids the problems of pin-type connectors which have been employed heretofore.

In actual utilization of the coupler described, it is impossible to completely eliminate electromagnetic radiation which might be detected by a nearby intruder, such as an enemy submarine. Accordingly, it would be highly desirable if the coupled data could be encrypted in a manner that would avoid useful decoding of the coupled data.

In my co-pending patent application Ser. No. 258,349, a random number generator, located within an aircraft, generates a random number which is coupled to the sending unit of the coupler, and from there to a data generator. This random number serves to encode the data which is ultimately transmitted, as encrypted data, to the pick-up unit, via the sending unit. Once the encrypted data is received by circuitry within the aircraft, it is decoded in the same sequence as it was encoded during encryption.

Accordingly, if the random number alone or the encoded encrypted data is detected by enemy surveillance equipment, the true data itself cannot be decoded since the decoding sequence is only properly performed by compatible encoding and decoding equipment of the present invention.

Thus far, my co-pending applications have been described in terms of providing secure data. However, it is possible for unfriendly parties to employ available sensitive detection devices to detect radiated data signals emanating from internal aircraft cables connecting the data memory to the various data utilization devices within the aircraft. Accordingly, it is highly desirable to effect a method for masking the internal data signals in such a manner that would prevent useful radiation detection.

BRIEF DESCRIPTION OF THE PRESENT INVENTION

Modern fighter aircraft have the data provided in various subsets for a plurality of utilization devices on board the aircraft. In prior art systems, the various subsets are serially read into the various utilization devices from a data storage memory. The primary concept of the present invention is to provide the utilization devices with data subsets which are loaded in parallel so that any radiated data of each subset is masked by the other radiated superimposed subsets. More particularly, the masking occurs because each of the parallel subset paths generates a radiated signal which becomes superimposed with the other subset data which produces a resultant scrambled signal which is extremely difficult to process for retrieval of the individual data subsets.

BRIEF DESCRIPTION OF THE FIGURES

The above-mentioned objects and advantages of the present invention will be more clearly understood when considered in conjunction with the accompanying drawings, in which:

FIG. 1 is a diagrammatic illustration of the installation of a data coupler on an aircraft skin;

FIG. 2 is a cut-away diagrammatic view of a magnetic induction sending and pick-up pair, constituting a coupler, for which the present invention is intended;

FIG. 3 is a diagrammatic elevational view of a section of an aircraft skin to which a sending unit, such as shown in FIG. 2, is attached;

FIG. 4 is a block diagram of the random number system of my co-pending application; and

FIG. 5 is a block diagram of the parallel data distribution system in accordance with the present invention.

DETAILED DESCRIPTION OF THE INVENTION

Prior to a discussion of the present parallel data distribution as depicted in FIG. 5, a detailed description of the signal coupling system of my, mentioned co-pending patent application Ser. No. 258,349 will be discussed.

FIG. 1 is a diagrammatic view showing the coupler of my co-pending application, shown installed on an aircraft skin. The portable code box discussed in the Background of the Invention is indicated as an external data/power generator 10 in FIG. 1. Such an external generating generator has long been used in the prior art. In addition to being able to read out stored data, the genera-
ator 10 is supplied with a switch (Power Inverter) that
initially powers an internal aircraft memory circuit
when the aircraft’s own power is off, thereby enabling a
memory to start its data storage operation and send
confirmation control signals back to the generator 10.
This is a great advantage as loading can take place at
any time prior to launch even without aircraft power or
ground power on.

The coupling of power and data from the generator
10 includes a cable 13 connected at a first end to genera-
tor 10 and at an opposite end to a sending unit 14. For
example, such a unit may be an inductive primary unit
as shown in FIG. 2 and discussed hereinafter.

The sending unit 14 is equipped with a circular mag-
netic ring 24, which may be of the gasket type used in
home refrigerators. A mating magnetic ring 18 is appro-
priately cemented to the internal surface of an aircraft
skin 16. The sending unit 14 is detachable from the
aircraft skin by simply exerting sufficient tension. Of
course, other types of temporary attachment may be
employed such as suction, velcro, etc.

A complementary inductive pick-up unit 19 may be
permanently cemented to the interior surface of the
aircraft skin 16 or it may be temporarily mounted by
utilizing ring magnets or the like, as just discussed in
connection with the sending unit 14. Signals sent from
generator 10 through the sending unit 14 are induct-
vitively picked-up by the pick-up unit 19 and transferred
to an internal data memory 12 by means of a cable 20.

In operation of the device illustrated in FIG. 1, the
power may be supplied from the external data/power
generator 10 to the internal data memory 12 in order to
power the memory circuits if the aircraft power supply
is turned off. The data memory circuits 12 are of the
type that already exist aboard military aircraft. After the
memory circuits have been sufficiently energized, the
generator 10 may be switched to a data transmission
mode so that the sending unit and pick-up units 14 and
19, respectively, may couple the data to the data mem-
ory 12.

The particular structure of the inductive coupling
units 14 and 19 are illustrated in greater detail in FIG. 2.
However, it is to be emphasized that other types of
sending and pick-up units, other than the particular
inductive units illustrated in FIG. 2, may be employed.
For example, other types of magnetic, capacitive, sonic
or vibratory transducers are technically feasible.

The particular magnetic inductance units shown in
FIG. 2 include a sending unit 14 having a ferromagnetic
housing 22 with a ring magnet, preferably a rubber
gasket type ring magnet 24 cemented around the bot-
tom periphery thereof. The magnet is for detachable
connection to the aircraft skin by means of the magnets
internally cemented thereto, as previously mentioned. A
cylindrical ferromagnetic coil form is axially disposed
within the housing 22 and serves as a core for windings
28 also located within the housing. The winding 28
serves as a primary winding and cooperates with a
secondary winding, located within the pick-up unit 19,
as will be discussed hereinafter. An electromagnetic
field is created between the primary winding 28, core 26
and the housing 22.

The pick-up unit 19 includes a similar structure,
namely, a central ferromagnetic core 32 with a second-
ary winding 38 secured thereto and a ferromagnetic
housing 30 which may be opened on the illustrated top
end 34 to allow the sending structure to be cemented, at
this end, to the interior surface of an aircraft skin. Alter-
nately, this end may be enclosed and detachably
mounted to the interior surface of an aircraft skin by
means of ring magnets, as discussed in connection with
FIG. 1. The opposite end 36 of the pick-up unit 19 is
closed. An electromagnetic field is created between the
cores 26 and 32 via housings 22 and 30. When the send-
ning and pick-up units are positioned on opposite sides of
an aircraft skin, the two units are inductively coupled
and magnetic flux lines link the two, as indicated by
reference numeral 40.

In order to minimize power dissipation of the coupled
signal and power, it would be preferable to have the area
of the aircraft skin between the sending and pick-
up units fabricated from a non-conducting material. This
is a preferable design consideration when high frequen-
cies are employed or otherwise, unwanted eddy cur-
rents may develop. In order to maximize the structural
connection of a non-conductive area to a conductive
aircraft skin, a slotted configuration as shown in FIG. 3
may be employed. In this figure, an area of the aircraft
skin 16 has a star-shaped slot 42 cut therein. The void
created is filled with a non-conductive material, such as
fiberglass, so as to completely fill the slot as indicated by
reference numeral 44. The slot itself is characterized
by pointed projections 44 interconnected around a cir-
cular boundary 46. The utilization of the pointed pro-
jections increases the electrical and electromagnetic
resistance of the aircraft skin in the vicinity of installa-
tion for sending and pick-up units which results in a
decrease of power dissipation between the sending and
pick-up units. In addition, the projections serve to me-
chanically interlock the non-conductive material 48 to
the aircraft skin 16, this being an important considera-
tion in the harsh environment encountered along the
outer skin of a military high-speed aircraft.

The center of the filled-in slot may have a central spot
50 painted thereon so as to guide the center placement
of the sending unit 14 when data and power are to be
inductively coupled.

Although a simplified inductive coupling is illus-
trated in connection with the sending and pick-up units,
it is also possible to use multiple coils to separate the
coupled signal and power so that two distinctive cou-
pling paths are the result.

Security of the described system is increased by the
random number system of my co-pending patent appli-
cation Ser. No. 258,349. In operation of that system as
illustrated in FIG. 4, the operational sequence generally
begins after power is coupled to the internal data mem-
ory 12 as previously discussed. Afterwards, the data
generator 10 couples a start command to the control
circuits of memory 12 in a conventional manner. A
random number generator 51 located within the aircraft
generates a random number and outputs it to the pick-
up unit 19. Since the pick-up unit and sending unit are
symmetrical and inductively coupled devices, the pick-
up unit acts as a primary at this time, while the sending
unit 14 acts as a secondary. The random number be-
comes stored in buffer 52 which is located in the data
generator 10. The data stored in memory 55 and the
random number are encoded in an encoder 54 in accor-
dance with a specific sequence. The encoded data now
represents an encryption of the basic data by the ran-
dom number. Wire 53 connects the output of encoder
54 to the sending unit 14 so that the encoded data may
be coupled to the pick-up unit 19. The latter unit then
outputs the encoded data to buffer 56 within the air-
craft. A decoder 58 has its inputs 60, 62 respectively

www.FreePatentsOnline.com
connected to the random number generator and the encoded data buffer so that the encrypted data may be decoded in accordance with the same specific sequence governing the encoder 54. The output 64 of the decoder then delivers the decoded data to the internal data memory 12 for use by other data or communication equipment on board the aircraft in a conventional fashion. To further enhance the security of communication, it is intended that each aircraft generate a different random number when the data generator 10 is coupled to succeeding aircraft.

The present invention is a further improvement of the systems disclosed in my co-pending applications and provides parallel distribution of data subsets to a plurality of utilization devices so that any radiated data signals will be superimposed to produce a resultant jumbled signal which effectively masks the data of each subset.

In order to better appreciate the concept of the present invention, reference is made to FIG. 5. As will be seen from the figure, the memory 12 stores a plurality of data subsets in locations 66, 68 and 70, by way of example. In a preferred embodiment of the present invention, memory 12 is a non-volatile RAM. The data subsets have been provided from the originating data source, via the sending and pick-up units. Connecting cables 72, 74 and 76 are connected from respective subset output ports of memory 12 to corresponding input ports of local memories 78, 80 and 82. Each of the latter-mentioned local memories serves to store one of the data subsets for a corresponding utilization device. The indicated utilization devices 84, 86 and 88 are respectively connected to their local memories by the parallel connecting cables 90, 92 and 94; and data will flow therebetweeen as the utilization devices require. With the simultaneous parallel flow of data along cables 72, 74 and 76, any resulting radiation outside the aircraft will be detected, by unfriendly surveillance, as superimposed unintelligible signals representing the parallel distributed data subsets. In addition, the noise present along the various parallel data channels is superimposed to increase the unintelligibility of the detected signal. Shielded cables 72, 74 and 76 are typically long "spider" cables which have a tendency to radiate signals; and the present invention is directed to obviate this problem.

Further enhancements for increasing the security of the system are to load the local memories with the various data subsets at different frequencies and signal amplitudes. Also, it is possible to encrypt the data as it is distributed from the memory 12 to the local memories.

As will be appreciated from an understanding of the present invention, there is offered a parallel data distribution system which creates electromagnetic radiation characterized as a superposition of the radiation for corresponding data subsets. A resultant scrambled signal is difficult, if not impossible to decipher by unfriendly surveillance equipment. Accordingly, the present invention enhances the security of data distribution within a military aircraft.

It should be understood that the invention is not limited to the exact details of construction shown and described herein for obvious modifications will occur to persons skilled in the art.

I claim:

1. A method for securing aircraft data distribution from electromagnetic radiation detection, the method comprising the steps:
   - coupling data from a data source outside the aircraft to a central non-volatile memory for storage of data subsets;
   - loading a plurality of remote local memories from the central memory in parallel with corresponding data subsets, whereby any electromagnetic radiation from data loading results in a scrambled superimposed radiation signal from all the subsets from which the individual data subsets cannot be detected; and
   - individually parallel loading the data subsets from the local memories to corresponding utilization devices.

2. The method set forth in claim 1 wherein the central memory is a non-volatile RAM.

3. A data security distribution system comprising:
   - pick-up means for receiving data coupled to the aircraft from a data source located externally of the aircraft;
   - a central memory having its input ports connected to the output of the pick-up means for storing a plurality of coupled data subsets;
   - a plurality of local memories connected in parallel to output ports of the central memory for loading the data subsets into corresponding local memories; whereby any electromagnetic radiation from data loading results in a scrambled superimposed radiation signal from all the subsets from which the individual data subsets cannot be detected; and
   - a plurality of means for individually connecting the data subsets in parallel to respective utilization devices.

4. The structure set forth in claim 3 wherein the central memory is a non-volatile RAM.
